Optical DNA-chip is widely used to study genome, gene expression and genetic diseases [1] We can divide it into three basic components: the sensing element or probe specific for target gene (single strand DNA); the labeling system, provided by conventional fluorophore CY5 (indodicarbocyanine) [2]; the optical detector, i.e. imagers or scanners. The labeling organic fluorophores exhibiting absorption/emission peaks very close, ~ 20 nm apart. Unfortunately, their prolonged exposure to laser light causes photo bleaching [3]. Moreover, their short lifetime, below 3 ns [4], could be an obstacle for the design of a miniaturized device, since a complex and fast (in the GHz range) electronic management system may be needed. In order to achieve the goal of a miniaturized, cheap and “simple” optical biosensor, we characterized an organometallic fluorophore, the tris(2,2'-bipyridyl)ruthenium(II) (Ru(bpy)₃²⁺). Our studies revealed that Ru(bpy)₃²⁺ emission properties (peak and lifetime) strongly depend from the chemical and physical environment. In particular we found an additional emission peak at 590 nm which dominates in the dried form regardless of the surface used to deposit the sample, while the lifetime value increases of a factor ten to ~30 ns. In order to understand the relation between the fluorophore form and its optical properties we firstly performed a full structural characterization through Low-Energy Scanning Transmission Electron Microscopy (STEM), operated at 60keV, by using a Cs corrected TEM JEOL ARM 200F. STEM analysis, of pure drop casted water solution containing Ru(bpy)₃²⁺ Thanks the very high sensitiveness of HAADF no negative staining, such as heavy uranyl acetate, was necessary. STEM observation in conjunction with chemical mapping performed by Electron Energy Loss Spectroscopy (EELS) and Energy Dispersive X-Ray Analysis (EDX), allowed us to identify fluorophore clusters of few nanometers, Figure 1, and to find a possible explanation for optical properties of the dried form. We than moved at the 200keV of beam energy, and for the first time we observed the single atoms of Ru, which are the direct evidence of the actual presence and the amount of molecules and their distribution on the substrate, Figure 2,. Motion of such single atoms has been also observed and studied under the electron beam radiance. For this study, a state-of-the-art aberration-corrected microscope installation at Beyond-Nano sub-Ångstrom Lab, in Catania, Sicily, Italy, has been used. This consists of a probe corrected STEM microscope equipped with a C-FEG and a fully loaded GIF Quantum ER as EELS spectrometer. This particular installation is capable to deliver a probe size of 0.68 Å at 200kV, and 1.1 Å at 60kV. Chemical mapping were extracted from the simultaneous acquired EELS and EDX spectra, by using the Spectrum Imaging mode.
